Introduction

We have a model which is governed by this equation :

$$dX_t = f(t, X_t, \theta)dt,$$

and the question is **how to find the parameter θ using the observations ?**

Introduction

From this model we have the function f , the time t and some observations Y which are modelised with some noise (that we may don't know). That's why I transform the equation in :

$$dX_t = f(t, X_t, \theta)dt + \sigma dB_t$$

The unknown is θ and maybe σ too.

An example : the Lotka Volterra model

$$dX_t = f(t, X_t, \theta)dt$$

The problem that I used to test the theory is the Lotka-Volterra model :

$$\begin{cases} \frac{dS}{dt} = S(\alpha - \beta W) \\ \frac{dW}{dt} = -W(\delta - \gamma S). \end{cases}$$

So here the unknown are $\theta = (\alpha, \beta, \gamma, \delta)$, $X = (S, W)$ and f does not depend on t .

Likelihood

So we are working with :

$$dX_t = f(t, X_t, \theta)dt + \sigma dB_t$$

$$L(\theta) = p(x_{t_0}, t_0; \theta) \prod_{i=1}^n p(x_{t_i}, t_i \mid x_{t_{i-1}}, t_{i-1}; \theta)$$

where p is the probability to obtain x_{t_i} at t_i knowing $x_{t_{i-1}}$ when f is parametrized by θ . So its log-likelihood becomes :

$$l(\theta) = \log(p(x_{t_0}, t_0; \theta)) + \sum_{i=1}^n \log(p(x_{t_i}, t_i \mid x_{t_{i-1}}, t_{i-1}; \theta))$$

Likelihood

We will use this formula :

$$l(\theta) = \log(p(x_{t_0}, t_0; \theta)) + \sum_{i=1}^n \log(p(x_{t_i}, t_i \mid x_{t_{i-1}}, t_{i-1}; \theta))$$

and we are looking for the maximum likelihood estimator

$$\hat{\theta}_n = \arg \max_{\theta \in \Theta} l(\theta).$$

Likelihood

To find $\hat{\theta}_n$ we need to simplify a little bit the log-likelihood. To do so we need to do quite simple approximations : Euler approximation :

$$X_{t_{i+1}} = X_{t_i} + f(t_i, X_{t_i}, \theta)(t_{i+1} - t_i) + \sigma(B_{t_{i+1}} - B_{t_i}).$$

So we can find p (B is a brownian motion) :

$$p(x_{t_i}, t_i \mid x_{t_{i-1}}, t_{i-1}; \theta) \sim \mathcal{N}(x_{t_{i-1}} + f(t_{i-1}, x_{t_{i-1}}, \theta)(t_i - t_{i-1}), (\sigma^t \sigma)(t_i - t_{i-1}))$$

and the log-likelihood becomes

$$l(\theta) = -\frac{1}{2} \sum_{i=1}^n \left(\frac{(x_{t_i} - x_{t_{i-1}} - f(t_{i-1}, x_{t_{i-1}}, \theta)(t_i - t_{i-1}))^2}{\sigma^2(t_i - t_{i-1})} + \log(2\pi\sigma^2(t_i - t_{i-1})) \right).$$

Likelihood

Now I did a hypothesis, I supposed that $\exists \Delta t \forall i, t_i - t_{i-1} = \Delta t$ so that the log-likelihood becomes :

$$l(\theta) = -\frac{1}{2} \sum_{i=1}^n \left(\frac{\|\sigma^{-1}(x_{t_i} - x_{t_{i-1}} - f(t_{i-1}, x_{t_{i-1}}, \theta)(t_i - t_{i-1}))\|_2^2}{(t_i - t_{i-1})} + \log((2\pi)^n \det(\sigma)^2 (t_i - t_{i-1})) \right).$$

So to maximize the log-likelihood is to maximises the previous equation.

Likelihood

So the new problem is how to minimise :

$$S(\theta) = \sum_{i=1}^n \|\sigma^{-1}(x_{t_i} - x_{t_{i-1}} - f(t_{i-1}, x_{t_{i-1}}, \theta)(\Delta t))\|_2^2.$$

and this is much more easy.

Remark : So, in our case, the max-likelihood estimator is the least squared estimator.

The Gauß-Newton method

The main idea of this method is to apply a Newton method to the derivative of S .

$$\theta^{(\text{new})} = \theta - \text{Hess}_\theta(S)^{-1} \nabla_\theta(S)$$

This isn't the relation that we can find on Wikipedia when we search "Gauß-Newton method", so we rewrite S as

$$S(\theta) = \sum_{k=1}^n r_k^2(\theta).$$

So $r_k = \|\sigma^{-1}(x_{t_k} - x_{t_{k-1}} - f(t_{k-1}, x_{t_{k-1}}, \theta)(\Delta t))\|_2$ and we found :

$$\text{Hess}_\theta(S)_{i,j} = \sum_k 2r_k \frac{\partial^2 r_k}{\partial x_i \partial x_j} + 2 \frac{\partial r_k}{\partial x_i} \frac{\partial r_k}{\partial x_j}.$$

The Gauß-Newton method

The formula that we found need the approximation (I have no main argument to justify it)

$$\left| r_k \frac{\partial^2 r_k}{\partial x_i \partial x_j} \right| \lll \left| \frac{\partial r_k}{\partial x_i} \frac{\partial r_k}{\partial x_j} \right|.$$

So the hessian can be rewritten as :

$$\text{Hess}_\theta(S)_{i,j} = 2 \sum_k \frac{\partial r_k}{\partial x_i} \frac{\partial r_k}{\partial x_j}.$$

The Gauß-Newton method

$$\theta^{(\text{new})} = \theta - \underbrace{\text{Hess}_{\theta}(S)^{-1}}_{(2\text{Jac}_{\theta}(\mathbf{r})^{\top} \text{Jac}_{\theta}(\mathbf{r}))^{-1}} \underbrace{\nabla_{\theta}(S)}_{2\text{Jac}_{\theta}(\mathbf{r})^{\top} \mathbf{r}}.$$

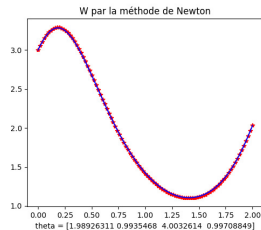

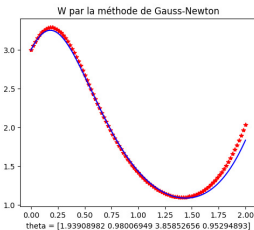

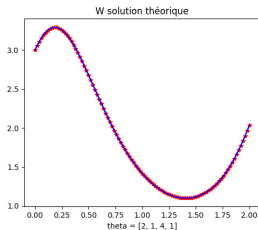

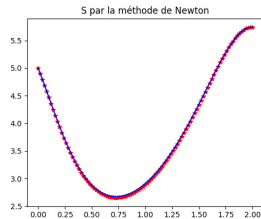

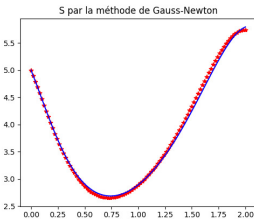

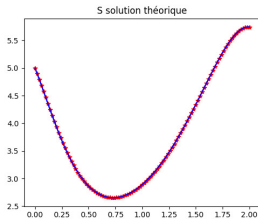

So the formula, which describes the Gauß-Newton method is :

$$\theta^{(\text{new})} = \theta - (\text{Jac}_{\theta}(\mathbf{r})^{\top} \text{Jac}_{\theta}(\mathbf{r}))^{-1} \text{Jac}_{\theta}(\mathbf{r})^{\top} \mathbf{r},$$

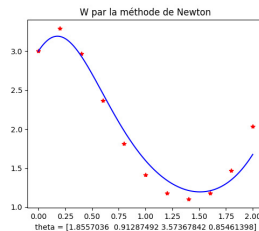

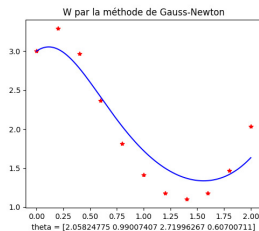

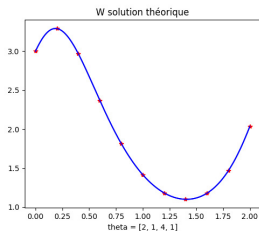

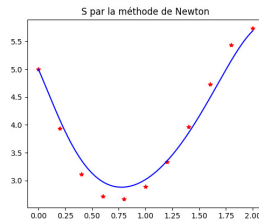

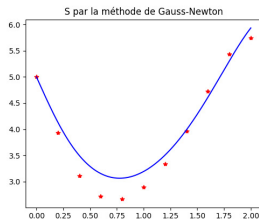

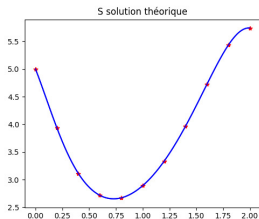

where

$$\mathbf{r} = \begin{pmatrix} r_1 \\ \vdots \\ r_n \end{pmatrix}.$$

The Gradient descent method

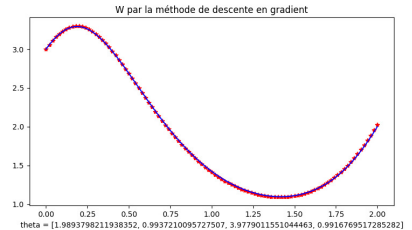

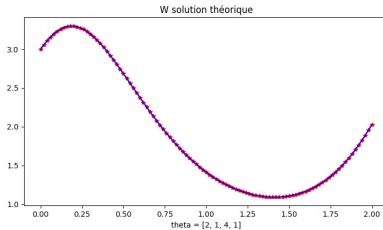

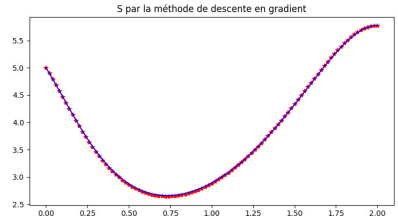

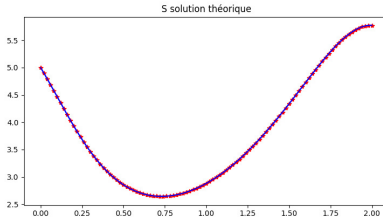

This algorithm uses this formula :

$$\theta^{(\text{new})} = \theta - \alpha' \nabla_{\theta} S$$

where $\nabla_{\theta} S$ is the gradient of S at θ and α' need to be determined.
We choose α' such that :

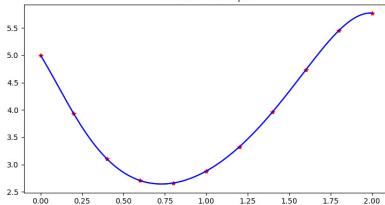

$$\alpha' = \arg \min_{\alpha \in \mathbb{R}} \{S(\theta - \alpha \nabla_{\theta} S)\}$$

The Levenberg-Marquardt method

If we come back to the Gauß-Newton formula and if we note $F = X - f(t, X; \theta)$ we have :

$$(\text{Jac}_\theta(F)^\top \text{Jac}_\theta(F))(\theta^{(\text{new})} - \theta) = \text{Jac}_\theta(F)(X - F).$$

To make the notations easier we will replace $\text{Jac}_{\theta^{(k)}}(F)$ by \mathbf{J} .
The Levenberg-Marquardt method consists to add a term (and there are two possibles) :

$$\begin{aligned}(\mathbf{J}^\top \mathbf{J} - \lambda \text{Id})(\theta^{(\text{new})} - \theta) &= \mathbf{J}(X - F) \\ (\mathbf{J}^\top \mathbf{J} - \lambda \text{diag}(\mathbf{J}^\top \mathbf{J}))(\theta^{(\text{new})} - \theta) &= \mathbf{J}(X - F)\end{aligned}$$
